Grain-oriented (GO) silicon steel laminations are widely used in iron cores and shielding structures of power equipments. When the leakage magnetic flux is very strong and enters the lamination plane perpendicularly, the eddy current loss induced there must be taken into account in electromagnetic design. It is preferable to accurately compute three-dimensional (3D) eddy currents at least in a few outer sheets of the lamination stack. Since the coating film applied to each sheet is only 2-5µm thick, finite element modeling of 3D eddy currents is very difficult in GO silicon steel laminations of large electromagnetic devices. This paper proposes an inner-constrained separation technique (ICST) to compute the 3D eddy currents. Instead of the coating film, the ICST introduces an inner-constrained separation technique (ICST) to separate the laminations from each other. By the ICST, the 3D eddy currents can be computed accurately without meshing the coating film. Numerical experiments are carried out on the TEAM (Testing Electromagnetic Analysis Methods) benchmark model P21—M1 and the numerical results show good agreements with the measured data.

Index Terms—Eddy currents, finite element methods, GO silicon steel lamination, inner-constrained separation technique.

I. INTRODUCTION

GRAIN-ORIENTED (GO) silicon steel laminations are widely used in iron cores and shielding structures of power equipments. The lamination stack usually consists of many steel sheets (0.18-0.35mm thick) and very thin coating films (2-5µm thick). Thus the lamination stack has multi-scale sizes and the ratio of the largest scale to the smallest scale can amount to 10³. Full 3D finite element modeling is extremely difficult due to large numbers of elements from meshing both laminations and coating films.

In recent years, numerical methods have been widely studied for nonlinear eddy current problems in steel laminations. Among them, most works pay attention to effective reluctivities and conductivities of the lamination stack (cf. e.g. [1]–[5]). The main idea is to replace physical parameters with equivalent (or homogenized) parameters for Maxwell’s equations. In [6]–[7], Bottauscio et al propose a mathematical homogenization technique based on the multiple scale expansion theory to derive the equivalent electric parameters and effective magnetization properties. In [8]–[9], Gyselinck et al deduce the effective material parameters by an orthogonal decomposition of the flux in the perpendicular and parallel directions to the lamination plane. In [10], Napieralska-Juszczak et al establish equivalent characteristics of magnetic joints of transformer cores by minimizing the magnetic energy of the system. Numerical methods based on the homogenization of material parameters provide an efficient way to simulate electromagnetic field in steel laminations. Since the effective conductivity is anisotropic and has zero value in the normal direction to the lamination plane, the numerical eddy current is thus two-dimensional in the lamination stack.

When the leakage magnetic flux is very strong and enters the lamination plane perpendicularly, for example, in the outer laminations of large power transformer core, the eddy current loss induced there must be taken into account in electromagnetic design. It is preferable to accurately compute 3D eddy currents at least in a few outer sheets of the lamination stack, that is, to use the zoned treatment for practical approaches, see Fig. 1. In such an accurate finite element analysis, one usually has to mesh both the laminations and the coating films in the 3D eddy current region. In [11], Cheng et al present an efficient macroscopic modeling method for iron cores. By meshing the laminations and the coating films in the 3D eddy current region, they investigated the effects of the eddy current, induced by the normal magnetic field, on the total iron loss and the distortion of the local magnetic flux in the laminations. More recently, some scientists paid attention to the study of the loss spectrum and electromagnetic behavior of laminated steel sheets in the literature (cf. e.g. [12]–[17]).

Fig. 1 Zoned treatment of the lamination stack. The six laminations close to the source have isotropic conductivity and are meshed individually.

The main objective of this paper is to propose an inner-constrained separation technique (ICST) for the finite element computation of 3D eddy currents in silicon steel laminations. The eddy current is confined in each lamination by the coating film. The treatment of this property plays the key role in
designing efficient numerical methods for computing 3D eddy currents. The standard approach is to mesh the coating film and set the conductivity to zero there (see [11]). It usually leads to very anisotropic meshes and large numbers of elements, and as a result, the discrete problem will be very difficult to solve. The ICST introduces an inner constraint on the magnetic vector potential to replace the coating film so that the eddy current is still conserved in each lamination. The main merit is that it need not partition the coating film in finite element modeling.

The finite element approximation of the nonlinear eddy current problem is solved by an inexact Newton method and an alternating iteration algorithm. We implement the ICST finite element method based on MPI (Message Passing Interface) and unstructured tetrahedral meshes. The proposed method and the parallel program are tested by the TEAM Benchmark Problem 21 c–M1. The numerical results show good agreements with the measurement data.

II. THE A-FORMULATION OF EDDY CURRENT PROBLEMS

In the A-formulation of the eddy current model, \( A \) denotes the magnetic vector potential satisfying \( \text{curl} A = 0 \) and \( B = \text{curl} A \) be the magnetic flux density. Then the A-formulation of the eddy current model reads (cf. e.g. [18]):

\[
\sigma \frac{\partial A}{\partial t} + \nu \text{curl} A = J_s \quad \text{in} \quad \Omega,
\]

\[
A \times n = 0 \quad \text{on} \quad \Gamma
\]

where \( \sigma \) is the electric conductivity, \( \nu \) is the nonlinear and anisotropic reluctivity, and \( J_s \) stands for the exciting source satisfying \( \text{div} J_s = 0 \). Let \( \Omega \) be the truncated domain with boundary \( \Gamma \) and \( n \) be the unit outer normal of \( \Gamma \). The weak formulation of (1) reads: Find \( A \in H_0(\text{curl},\Omega) \) such that

\[
\int_\Omega \sigma \frac{\partial A}{\partial t} \cdot v + \int_\Omega \nu \text{curl} A \cdot \text{curl} v = \int_\Omega J_s \cdot v
\]

\[
\forall \ v \in H_0(\text{curl},\Omega),
\]

where \( v \) is the test function and

\[
H(\text{curl},\Omega) = \left\{ u \in L^2(\Omega) : \text{curl} u \in L^2(\Omega) \right\},
\]

\[
H_0(\text{curl},\Omega) = \left\{ u \in H(\text{curl},\Omega) : u \times n = 0 \text{ on } \Gamma \right\}.
\]

Throughout this paper, we shall denote vector-valued quantities by boldface notation, such as \( L^2(\Omega) = (L^2(\Omega))^3 \), where \( L^2(\Omega) \) is the space of square-integrable functions. Furthermore, we also define

\[
H^1(\Omega) = \left\{ u \in L^2(\Omega) : \nabla u \in L^2(\Omega) \right\},
\]

\[
H^1_0(\Omega) = \left\{ u \in H^1(\Omega) : u = 0 \text{ on } \Gamma \right\}.
\]

First we study the conservation property of eddy currents in steel laminations. It will provide the inspiration for deriving a new A-formulation which replaces the coating film with the ICST. Let \( \Omega_c \subset \Omega \) denote the conducting region which consists of \( M \) laminations, namely,

\[
\Omega_c = \Omega_1 \cup \cdots \cup \Omega_M.
\]

Since the coating film has positive thickness, \( \Omega_1, \cdots, \Omega_M \) are viewed as isolated conductors (see Fig. 2), that is,

\[
\text{distance}(\Omega_i, \Omega_j) > 0 \quad \text{for} \quad i \neq j.
\]

Let \( J = \sigma \frac{\partial A}{\partial t} \) be the eddy current density. We state that the weak formulation (2) implies the conservation of \( J \) in each lamination. In fact, since \( \nabla H^1_0(\Omega) \subset H_0(\text{curl},\Omega) \), taking \( v = \nabla \varphi \) in (2) yields

\[
\int_\Omega J \cdot \nabla \varphi = 0 \quad \forall \ \varphi \in H^1_0(\Omega),
\]

which by (3) is equivalent to

\[
\int_{\Omega_i} J \cdot \nabla \varphi_i = 0 \quad \forall \ \varphi_i \in H^1(\Omega_i), \quad 1 \leq i \leq M.
\]

Then using integration by parts and the arbitrariness of \( \varphi_i \), we obtain the conservation of \( J \) in each \( \Omega_i \):

\[
\begin{align*}
\text{div} J &= 0 \quad \text{in} \quad \Omega_i, \\
J \cdot n &= 0 \quad \text{on} \ \partial \Omega_i, \quad 1 \leq i \leq M.
\end{align*}
\]

The conditions in (6) indicate that the eddy currents, or the laminations, are separated by the coating film. Numerical methods for computing 3D eddy currents should satisfy these conditions. In the next section, we shall assume that the thickness of the coating film is zero and derive a new A-
formulation satisfying (6). The idea is to separate the laminations by an inner constraint instead of the coating film. It is thus named as the “Inner-Constrained Separation Technique”.

III. A NEW $A$-FORMULATION BASED ON ICST

Now we suppose that the thickness of the coating film is zero (see Fig. 3). Then we have

$$
\Omega_c = \bigcup_{i=1}^{M} \Omega_i, \quad \text{distance}(\Omega_i, \Omega_{i+1}) = 0.
$$

Remember from (6) that the conservation of $\mathbf{J}$ is ensured by (5). Now for $\Omega_c$ satisfying (7), equation (5) is equivalent to

$$
\int_{\Omega} \mathbf{J} \cdot \nabla \varphi = 0 \quad \forall \varphi \in H^1_0(\Omega),
$$

$$
\int_{\Omega_i} \mathbf{J} \cdot \nabla \varphi_i = 0 \quad \forall \varphi_i \in H^1(\Omega_i) \text{ and even } i.
$$

A comparison of (8) and (5) indicates that the test function space should contain the gradient of every $\varphi$ for even index $i$. Thus the test function space in (2) is enlarged from $H_0^1(\Omega)$ to $H_0^1(\Omega_i)$ for even index $i$. For $\Omega_c$ satisfying (7), we propose a new $A$-formulation as follows: Find $A \in H_0^1(\Omega)$ and $u \in U$ such that

$$
\int_\Omega \sigma \frac{\partial (A + u)}{\partial t} \cdot (v + w) + \int \nabla v \cdot A \cdot \nabla v = \int_\Omega \mathbf{J} \cdot (v + w) \quad \forall v \in H_0^1(\Omega), \ w \in U,
$$

where $v, w$ are test functions and the magnetic reluctivity $\nu$ depends on the flux density $B = \text{curl } A$. In fact, $u$ plays the role of an inner constraint on $A$ so that the current density $\mathbf{J} = \sigma \frac{\partial (A + u)}{\partial t}$ fulfils the conservation property in (6).

The constraint function $u$ can be solved by nodal element method only in $\Omega_i$ for even index $i$ (see Fig. 4). The merit of (10) is that the coating films do not appear in the computational domain and the isotropic conductivity $\sigma$ induces 3D eddy current in each lamination.

IV. FINITE ELEMENT APPROXIMATION

In this section, we study the finite element approximation to (10) and propose an inexact Newton method for solving the nonlinear discrete problem. First we divide the time interval $[0, t_{end}]$ into small ones

$$
0 = t_0 < t_1 < \cdots < t_M = t_{end},
$$

and let $\tau_n = t_n - t_{n-1}$ be the time step size at $t_n$. Let $\mathcal{T}_h$ be a tetrahedral mesh of $\Omega$ and define the nodal element space and the edge element space on $\mathcal{T}_h$ by

$$
Y_h = \left\{ v \in H^1_0(\Omega) : v|_T \in P_{k+1}(T) \quad \forall T \in \mathcal{T}_h \right\},
$$

$$
X_h = \left\{ v \in H_0^1(\Omega) : v|_T \in P_k(T) \quad \forall T \in \mathcal{T}_h \right\},
$$

where $P_k(T)$ is the space of polynomials of order $k > 0$ and $P_k(T) = (P_k(T))^3$. Similar to (9), we define the ICST-finite element space as follows

$$
U_h = \left\{ \chi \cdot \nabla \varphi_h : \varphi_h \in Y_h \right\}.
$$
Given $A_0 = u_0 = 0$, the fully discrete approximation to (10) reads: Find $A_n \in X_h$, $u_n \in U_h$, $n \geq 1$ such that

$$
\int_{\Omega} \sigma \frac{\delta(A_n + u_n)}{\partial t} \cdot (v_n + w_h) + \int_{\Omega} \nu \operatorname{curl} A_n \cdot \operatorname{curl} v_h \\
= \int_{\Omega} J_n \cdot (v_h + w_h) \quad \forall v_h \in X_h, w_h \in U_h,
$$

where $v_h, w_h$ are discrete test functions and

$$\frac{\partial w_n}{\partial t} = \frac{w_n - w_{n-1}}{\tau_n} , \quad J_n = \frac{1}{\tau_n} \int_{t_{n-1}}^{t_n} J(t) \, dt.$$

Let $\{b_1, \ldots, b_{J_1}\}$ and $\{q_1, \ldots, q_{J_2}\}$ be the nodal bases of $X_h$ and $U_h$ respectively. Then $A_n, u_n$ can be represented by the linear combinations of these basis functions:

$$A_n = \sum_{i=1}^{J_1} A_n^i b_i , \quad u_n = \sum_{i=1}^{J_2} u_n^i q_i.$$

Now taking $v_h = b_j, 1 \leq j \leq J_1$ and $w_h = q_j, 1 \leq j \leq J_2$ in (13) respectively, we get an equivalent system of algebraic equations

$$M(Z_n) \cdot Z_n = F_n,$$

where $Z_n = (A_n^1, \ldots, A_n^{J_1}, u_n^1, \ldots, u_n^{J_2})^T$ and $M(Z_n)$ is the stiffness matrix defined by

$$M_{ij} = \int_{\Omega} \sigma \frac{\delta A_n^i}{\partial t} \cdot \delta A_n^j \cdot \delta t + \int_{\Omega} \nu \operatorname{curl} A_n^i \cdot \operatorname{curl} A_n^j \cdot \delta t , 1 \leq i, j \leq J_1,$$

$$M_{i+J_1,j+J_1} = \int_{\Omega} \sigma \frac{\delta u_n^i}{\partial t} \cdot \delta u_n^j \cdot \delta t , 1 \leq i, j \leq J_2, \quad (15)$$

$$M_{i+J_1,i+J_1} = \int_{\Omega} \sigma \frac{\delta u_n^i}{\partial t} \cdot \delta q_j \cdot \delta t , 1 \leq i \leq J_1, 1 \leq j \leq J_2.$$

Clearly $M(Z_n)$ depends on $Z_n$ through the nonlinear reluctivity. The entries of $F_n$ are defined by

$$F_n^i = \int_{\Omega} (J_n + \tau_n^{-1} \sigma A_{n-1}) \cdot b_i , \quad 1 \leq i \leq J_1,$$

$$F_n^{i+J_1} = \int_{\Omega} (J_n + \tau_n^{-1} \sigma A_{n-1}) \cdot q_i , \quad 1 \leq i \leq J_2.$$

We are going to solve the nonlinear problem (14) by inexact Newton method (cf. e.g. [19, Section 1.4]):

$$Z_n^{(k+1)} = Z_n^{(k)} + \alpha_k \tilde{E} , \quad k \geq 0 , \quad Z_n^{(0)} = Z_{n-1} , \quad (16)$$

where $0 < \alpha_k \leq 1$ is the damping factor and $\tilde{E}$ is an approximate solution of the system of algebraic equations:

$$\tilde{M} \cdot E = R_{n,k}.$$

In fact, (17) is the error equation of (14) for the approximate solution $Z_n^{(k)}$, and $R_{n,k}$ is the residual vector defined by

$$R_{n,k} := F_n - M(Z_n^{(k)}) \cdot Z_n^{(k)}.$$

Let $(A_n^{(k)}, u_n^{(k)})$ be the approximate solutions of (13) associated with $Z_n^{(k)}$. The matrix $\tilde{M}$ is also computed by (15) and by replacing $\nu$ with the differential reluctivity $\hat{\nu}$ valued at $(A_n^{(k)}, u_n^{(k)})$. The inexactness of the Newton method means that a damping factor $\alpha_k$ and an approximate solution $\tilde{E}$ of (17) are used at each step.

**Algorithm 1 (Inexact Newton Algorithm)**

Given the maximal number of iterations $N_{\text{inad}} = 50$ and the initial guess $Z_n^{(0)} = Z_{n-1}$. Set $k = 0$.

While $\| R_{n,k} \| \geq 10^{-3} \| F_n \|$ & $\| R_{n,k} \| \leq N_{\text{inad}}$

1. Set $\varepsilon = 1 + \| R_{n,k} \|$ and $\alpha_k = 1/0.618$.

2. Compute an approximate solution $\tilde{E}$ of (17) by Algorithm 2.

3. While $\varepsilon \geq \| R_{n,k} \|$ do

   (3.1) $\alpha_k \leftarrow 0.618 \alpha_k$ ;

   (3.2) $Z_n^{(k+1)} = Z_n^{(k)} + \alpha_k \tilde{E}$ ;

   (3.3) $\varepsilon \leftarrow \| F_n - M(Z_n^{(k+1)}) \cdot Z_n^{(k+1)} \|$. 

End While.

4. $k \leftarrow k + 1$.

End While.

To the best of our knowledge, for large numbers of elements, efficient solver is still a difficult issue for discrete Maxwell’s equations with nonlinear and anisotropic reluctivity. Accurate solution of (17) requires a long time and makes the Newton method inefficient. To reduce the computational time, we only use an approximate error function $\tilde{E}$ in (16). The exact solution of (17) is denoted by $E = (E_1, \ldots, E_{J_1+J_2})$ and represents the error functions as follows.
\[ e = \sum_{j=1}^{J} E_j b_j, \quad \theta = \sum_{j=1}^{J} E_{j+1} q_j. \]

Then (17) is equivalent to the discrete problem: Find \( e \in X_h \) and \( \theta \in U_h \) such that

\[
\int_{\Omega} \tau_n (e + \theta) \cdot (v_h + w_h) + \int_{\Omega} \hat{\nabla} \text{curl} e \cdot \text{curl} v_h = r_{n,k}(v_h, w_h) \quad \forall v_h \in X_h, \ w_h \in U_h,
\]

where \( r_{n,k} \) is the residual functional defined by

\[
r_{n,k}(v_h, w_h) = \int_{\Omega} (v_h + w_h) - \int_{\Omega} \text{curl} \ A^{(k)} \cdot \text{curl} v_h - \int_{\Omega} \tau_n \left( A^{(k)} + u^{(k)} - A_{n-1} - u_{n-1} \right) \cdot (v_h + w_h).
\]

Now we propose an alternating iteration algorithm to compute an approximate solution \( \tilde{E} \) of (17).

Algorithm 2 (Alternating Iteration Algorithm)

Given the maximal number of iterations \( N_{\text{dia}} = 10 \) and the initial guess \( E_0 = 0 \) and \( e_0 = 0 \). Set \( l = 0 \).

1. While \( \| R_{n,k} - \tilde{M} \cdot E_l \| \geq 10^{-2} \| R_{n,k} \| \) & \( l \leq N_{\text{dia}} \) do

   1.1 Solve the following elliptic problem by 5 iterations of conjugate gradient method preconditioned by the Boomer-AMG (Algebraic Multigrid) method [20]:

   \[ \text{Find } \phi_{l+1} \in Y_h \text{ such that } \int_{\Omega} \chi \sigma \nabla \phi_{l+1} \cdot \nabla \varphi_h = \tau_n r_{n,k}(0, \chi \nabla \phi_h) - \int_{\Omega} \chi \sigma e_l \cdot \nabla \varphi_h \quad \forall \varphi_h \in Y_h. \]

   1.2 Solve the following Maxwell equation by 10 iterations of preconditioned conjugate gradient (PCG) method with the HX-preconditioner [21]:

   \[ \text{Find } e_{l+1} \in X_h \text{ such that } \int_{\Omega} \sigma e_{l+1} \cdot v_h + \tau_n \int_{\Omega} \hat{\nabla} \text{curl} e_{l+1} \cdot \text{curl} v_h = \tau_n r_{n,k}(v_h, 0) - \int_{\Omega} \chi \sigma \nabla \phi_{l+1} \cdot v_h \quad \forall v_h \in X_h. \]

   1.3 Compute \( E_{l+1} \) from \( (e_{l+1}, 0_{l+1}) \) and set \( l \leftarrow l + 1 \).

End While.

2. Set \( \tilde{E} = E_l \).

Since Algorithm 2 only computes an approximate solution of (17), to reduce the computational time, we set the maximal number of iterations by \( N_{\text{dia}} = 10 \). In each alternating iteration, we only use 5 iterations of PCG method for solving \( \phi_{l+1} \) and 10 iterations of PCG method for solving \( e_{l+1} \). Since the Boomer-AMG method is very efficient in solving second-order elliptic problems, we use less iterations in Step 1.1 than in Step 1.2. In fact, the computational time for Step 1.1 is negligible compared with that for Step 1.2.

V. NUMERICAL EXPERIMENTS

In this section, we report the numerical experiment based on the TEAM Workshop Problem 21®-M1 [22]. The conducting region, referred to as a magnetic shield configuration, is the combination of a lamination stack and a magnetic plate whose dimensions are respectively \( 6 \times 270 \times 458 \) mm\(^3\) and \( 10 \times 360 \times 520 \) mm\(^3\), as shown in Fig. 5. The lamination stack consists of 20 steel sheets and the coating film over each sheet is 4µm thick. The source currents are carried in opposite directions by two coils and are 3000 Ampere/Turn at a frequency of 50Hz, namely,

\[ J_1(x, t) = \hat{J}_1(x) \cdot \sin(100\pi t), \quad t \geq 0. \]

The height of each coil is 217mm and the radiuses of the inner arc and the outer arc at four corners are 10mm and 45mm respectively. The distance between the lamination stack and the coils is 12mm and the vertical distance between the two coils is 24mm.

![Fig. 5 TEAM Workshop Problem 21®-M1(all dimensions are in mm).](image)

We use the second-order edge element method of the second family [23] to solve the problem, that is, setting \( k = 2 \) in (11). The implementation is based on the adaptive finite element package “Parallel Hierarchical Grid” (PHG) [24].
The computations are carried out on 512 CPU cores on the cluster LSEC-III, the State Key Laboratory on Scientific and Engineering Computing, Chinese Academy of Sciences.

The domain $\Omega$ is meshed into $9.0 \times 10^6$ tetrahedra and each lamination is subdivided into three layers in the normal direction to the lamination plane. The number of degrees of freedom on the mesh is $1.26 \times 10^8$. The purpose of this experiment is as follows:
1. To validate the new $A$-formulation (10) of the eddy current model by reducing the influence of the numerical error.
2. To demonstrate the approximation of the finite element problem (13) to the continuous problem (10).
3. To examine 3D eddy currents in the lamination.

The end time is set by the length of two periods of the source current and is given by $t_{end} = 0.04$ s. The interval $[0, t_{end}]$ is partitioned uniformly into 80 time steps such that $\tau_n = 5 \times 10^{-4}$ s for all $n > 0$. Unlike isotropic materials, the anisotropic reluctivity influences the number of Newton iterations. The criterion $\| R_{a,k} - \hat{M} \cdot E_i \| < 10^{-3} \| R_{a,k} \|$ is not always satisfied in Algorithm 2, and in that case, we use 10 alternating iterations to save the computational time. Fig. 6 shows the number of Newton iterations to attain the criterion $\| R_{a,k} \| < 10^{-3} \| F_n \|$ at all time steps within the first period. The method converges slowly at $t_n = 0.01$ s, 0.02 s, 0.03 s, and 0.04 s.

To validate the new formulation (10), the numerical results are compared with the experimental data measured by the R & D center of Baoding Tianwei Group Co., LTD, China, which can be found in [22]. Figs. 7-8 show the calculated values of the magnetic flux density on a coarse mesh with 187,152 tetrahedra and a fine mesh with 9,000,628 tetrahedra. The numerical values from the coarse mesh have larger errors on a few points, while the numerical values on the fine mesh agree well with the measurement data. TABLE I shows the calculated iron loss on the fine mesh and the numerical value is close to the experimental value. The numerical experiment indicates that the new formulation (10), or the ICST, provides an accurate approximation to the original problem (2), and the discrete problem (13) is a good approximation to (10).

![Fig. 6 Number of Newton iterations such that the relative residual is less than $10^{-3}$.

Figs. 9-10 show the tangential component of the eddy current density in $\Omega_1$ and $\Omega_2$, respectively, where $\Omega_1$ is the lamination whose distance is $d_1 = (11.7 + 0.3i)$ mm from
the coils, \( i = 1, 2 \). The eddy current density in the second sheet is reduced considerably compared with that of the first sheet. Fig. 11 shows the eddy current density on one slice of the magnetic plate which is 2mm away from the lamination stack. It shows a shielded area by the lamination stack.

VI. CONCLUSION

An inner-constrained separation technique is proposed for computing 3D eddy currents in GO silicon steel laminations. The ICST yields a new A-formulation of the eddy current problem and is efficient in simulating 3D eddy currents without meshing coating films. A parallel finite element program is developed to solve the new formulation based on MPI and unstructured tetrahedral meshes.

ACKNOWLEDGMENT

The authors would like to thank Prof. Zhiming Chen, Prof. Linbo Zhang, Dr. Tao Cui of Academy of Mathematics and Systems Science, Chinese Academy of Sciences, for their valuable discussions and suggestions. This work was supported in part by the National Magnetic Confinement Fusion Science Program (Grant No. 2011GB105003), by China NSF under the grants 11031006 and 11171334, and by the Funds for Creative Research Groups of China (Grant No. 11021101).
